

5 SECURITY CONTROLS

for an Effective Security Operations Center (SOC)

www.alienvault.com

Why a Security Operations Center?

The world today is comprised of two types of organizations: those who have been breached, and those who do not yet know that they've been breached. The difference between these types of organizations is related to how soon the company can detect a breach and how effectively they can respond. An effective Security Operations Center provides the information necessary for organizations to efficiently detect threats and subsequently contain them. While eliminating the threats we face is an impossible goal, reducing the time it takes to respond and contain them is certainly achievable. With a focus on responding to and containing threats, it is possible to define a Security Operations Center in simple terms: **the technology and processes used to detect breaches and coordinate the appropriate response.**

Historical precedent has led most organizations to view Security Operations Centers as large, overhead-intensive situation rooms staffed by huge numbers of highly trained (expensive) employees. This perception is because the world has looked to the most security-advanced organizations (large financial institutions, telecommunications operators, and military organizations) as role models for establishing their security practices. And while it is important to learn what we can from these institutions, we should ask ourselves:

“ Do all organizations need to invest in the same way to detect breaches and coordinate responses? What are the threats my organization faces, and how do those that impact my investment priorities? ”

Establishing a Security Operations Center is a necessary step for an organization to be able to detect and efficiently contain a breach. Once you've determined you will establish a SOC, the next important question to ask is, "how can my organization most efficiently achieve this goal?" To answer this, it is important to take a critical assessment of your organization's existing capabilities.

- What technologies have we already deployed that might be of use?
- Are these technologies available to my security team?
- What capabilities do I have on my security team?
- What are the current time constraints on that team?
- What priority does the larger organization place on this project?

When establishing the Security Operations Center it is important that a realistic understanding of these constraints are considered to ensure that an effective solution is created. If technology already exists, but access to the data cannot be guaranteed due to political reasons, it is of little use. Similarly, if technology is acquired, but the overhead required for deployment, integration, and management is beyond the capabilities of the current employees (either because of a lack of skills or a lack of time), then it will be of little help.

Essential Security Controls

The detection of breaches becomes an extraordinarily difficult task if the security program is developed using the examples of a few sophisticated breaches. However, when considered in the abstract, the essential capabilities are quite fundamental. Securing an environment consists of answering a few basic questions around security controls:

- What assets do I have to protect?
- Which of my assets are vulnerable to attack?
- How are people attacking my assets?
- How will I know if a breach has occurred?
- What actions are going to have the most impact on my security posture?

Now, in a simple environment with only a few unsophisticated threats, this is not a difficult set of questions to answer. It is even possible to start evaluating these questions with manual processes and achieve a reasonable end result. However, it does not take much for the complexity of an environment to be beyond the scope of a manual process. For this, let us examine the technology that can be used to automate these tasks.

SECURITY CONTROL #1:

What Assets Do I Have to Protect?

- What systems are critical to the ongoing function of your company?
- Which systems are critical to the day-to-day tasks?
- What other systems do those critical systems rely on?
- Which systems manage and store sensitive information?

Having an understanding of the assets that your organization has is critical to prioritizing the efforts to respond to attacks and contain breaches. Being able to prioritize efforts to mitigate threats to a particularly critical system is essential for an effective Security Operations Center. Often, response policies and detection capabilities are broadly distributed without a good understanding of how they can be most effectively deployed with respect to business impact. A good understanding of the assets that are deployed and the services running on those assets is essential.

SECURITY CONTROL #1:

What Assets Do I Have to Protect?

Beyond the ability to prioritize efforts based on potential business impact, having a good understanding of the assets deployed in your cloud and on-premises environments can help prioritize technical response to observed threats. Hackers often start without any understanding of the technical layout of the system they are targeting. As such, a full breach will often start with a discovery or probing phase. In this phase, the attacker will scan the network and attempt to exploit known vulnerabilities on common services. Understanding what services are running on a particular host can allow observers of the attack to know whether it even has a chance of being successful; trying to exploit a Microsoft Windows vulnerability on a Unix machine has no chance of succeeding.

Getting an accurate view of the assets deployed and the services running on those assets is a very difficult problem. The IT operations team can sometimes provide a reasonable picture in an asset management system. However, these systems are hard to access and are often out of date. An automated solution to this problem is preferable to ensure that the rapid rate of change found in modern data centers is accurately pictured in the security operations center.

SECURITY CONTROL #1:

TO PERFORM ASSET DISCOVERY, THREE AUTOMATED APPROACHES CAN BE TAKEN:

PASSIVE NETWORK MONITORING

By passively monitoring the network, traffic hosts and installed software packages are enumerated, identifying the protocols and ports used in the captured traffic.

ACTIVE NETWORK SCANNING

Active scanning probes the network to try and elicit responses from machines. Based on the response, the tool will identify the machine and the software installed on the machine.

CLOUD ASSET DISCOVERY

Cloud asset discovery tools should provide direct hooks into the cloud infrastructure providers' APIs (such as AWS and Azure) to deliver visibility into your cloud environments.

These techniques can be employed individually or in concert with one another. Each approach requires different levels of access to the environments being inventoried; using a variety of approaches ensures that some information can be gathered even from tightly controlled environments.

A good solution will provide a flexible approach to asset discovery both in cloud and on-premises environments, leveraging the techniques listed above to provide the most accurate picture possible. In addition, it will provide a centralized mechanism for discovering assets in remote segments of the network. Even a moderately complex network topology can cause operators to be faced with difficult access procedures, requiring manual steps to discover assets in remote network segments and, adding to the long-term cost of managing the solution.

SECURITY CONTROL #2:

Which of My Assets Are Vulnerable to Attack?

- How are the services that I have running configured?
- How can they be accessed?
- Do any of them have known vulnerabilities that an attacker may be able to exploit?

Once you have a reasonable understanding of the assets deployed in your organization, it is important to understand where your weaknesses lie. When responding to an attack or breach, understanding how your organization may have been exploited is a critical factor in prioritization. Knowing that a particular system is vulnerable to attack may make the environment in which that system operates one of your top security priorities. For example, if a critical business process relies on an antiquated web server that cannot be updated due to functional concerns, additional efforts can be made to ensure that the web server is well protected from attacks. Or if a breach is detected on the same network segment as the web server, additional priority can be given to the incident response effort. It is not always feasible to remove a vulnerability in your system, but it is possible to understand where the vulnerabilities lie and what the impact might be if they were to be exploited. Having a good understanding where your weaknesses lie is essential to understanding your prioritization efforts to prioritize when faced with an attack or a breach.

SECURITY CONTROL #2:

Which of My Assets Are Vulnerable to Attack?

Vulnerability assessment is a difficult and time-consuming effort. The software that is deployed in our environments, whether in the form of web applications, middleware, or even the firmware in our devices, is all inherently vulnerable. Every piece of software has flaws that could potentially be exploited. This is largely due to the fact that security is often not considered during the software development process. Even if security were a consideration, new methods for attack are always being developed, making the software that was secure a year ago potentially vulnerable today. Because of the nature of this problem, vulnerability assessment is a continuous process, and ultimately a very difficult task to perform in an automated manner.

Understanding how a piece of software might be exploited often requires knowing how that software works, what types of data it accepts and what function it is supposed to perform. This is why the vulnerability assessment that is performed in our network environments simply tries to identify software packages that contain known vulnerabilities. Once the simplification of the scope of this task is done, automation can be performed.

In addition, significant vulnerabilities and threats persist in the cloud, just as with assets on-premises. Typical cloud vulnerabilities result from improperly patched systems, cloud asset misconfigurations, and poorly managed credentials, leading to common attacks such as SQL injections, account and service hijacking, and distributed denial of service (DDoS) attacks. Therefore, scanning for vulnerabilities in your cloud environments is as essential as scanning assets in your data center.

SECURITY CONTROL #2:

THE FOLLOWING APPROACHES CAN BE USED TO AUTOMATE VULNERABILITY ASSESSMENT

ACTIVE NETWORK SCANNING

An active network scan actively probes hosts using carefully crafted network traffic to elicit a response. This combination of the targeted traffic and the subsequent response allows an analysis engine to determine the configuration of the remote system and the software packages running on the system. This combined with a database of known vulnerabilities allows the analysis to produce a list of vulnerabilities that are present on the system.

HOST-BASED ASSESSMENT

Using access to the file system of a system, an analysis engine can perform a more accurate and comprehensive detection of vulnerabilities by inspecting the installed software and comparing the detected software packages with a list of known vulnerable software packages.

CLOUD VULNERABILITY SCANNING

A cloud vulnerability scanner discovers and scans all instances in your cloud environments. This scanning is typically automated and lets you know which of your assets in the cloud are actually vulnerable to the exploits being attempted. Having this information at your fingertips gives you the actionable information you need to protect your cloud environments.

As all of these methods rely on a database of known vulnerabilities, it is important that they are performed periodically. Researchers publish information about new vulnerabilities constantly, and having an up to date database is the only way to ensure that your analysis engine can detect all of the latest vulnerabilities.

As with asset discovery, the deployment of vulnerability assessment tools can be a logistical hurdle. A good solution will provide a flexible approach in tightly controlled environments, as well as provide for centralized management of the vulnerability assessment scans in environments with complex network topologies.

SECURITY CONTROL #3:

HOW ARE PEOPLE ATTACKING MY ASSETS?

- Is anyone attacking my systems?
- What techniques are hackers employing when trying to compromise my systems?
- Where are those attacks coming from?

Due to the nature of the Internet, there is not a single one of us who is not being attacked. Unlike the physical world, on the Internet it is quite simple for attackers to find us in an automated manner. The attacker may not know exactly whom they are attacking, but finding our front door is as simple as counting. Also unlike the physical world, an online automated attack against many systems is not any more expensive than an attack against a single system. As such, attackers are constantly scanning the Internet, blindly attacking any and all systems they can find. For example, a simple web server serving a web page for a private audience that had not been indexed by Google was faced with an average of 50 intrusion attempts every day. Every single one of us is constantly being attacked; understanding the nature, target, and sophistication of those attacks is critical when prioritizing our security efforts.

SECURITY CONTROL #3:

HOW ARE PEOPLE ATTACKING MY ASSETS?

Threat detection can be thought of as the inverse problem of vulnerability assessment. Vulnerability assessment is the methodology for finding known vulnerabilities in your system; threat detection is the means to identify the attacks that are targeting those vulnerabilities.

Some attacks target particular vulnerabilities with known payloads; these can easily be detected using signatures that can specifically identify those payloads. Other attacks are less well known and in these scenarios it can be possible to try and detect the technique the attacker is using to exploit the vulnerability. For example, when trying to exploit a buffer overflow vulnerability, the attacker must inject the software with a large amount of data to overflow the memory segment the program is using for a particular buffer. Once this is achieved, the attacker must then try to gain control of the execution of the program by writing machine instructions to the memory they have just overwritten. Since the attacker does not know the exact way their attack is going to be handled, they must put in some “room for error”; this is often achieved by using a long string of ‘no operation’ instructions that will be essentially ignored by the machine. This, however, leaves a nice fingerprint for threat detection tools to find—a large amount of data being passed to a program that contains a long string of ‘no operation’ instructions can be identified as a potential exploit attempt. Alternatively, it is possible to detect indicators of an attack or indicators of compromise.

SECURITY CONTROL #3:

HOW ARE PEOPLE ATTACKING MY ASSETS?

As discussed before, targeted attacks often start with a discovery phase where the attacker is trying to identify vulnerable assets in your network. Detecting that a particular host is trying to probe your system can be essential to later evaluating whether or not a potential attack from the same host is real. The last resort to detecting threats is trying to detect indicators of compromise.

As with the other security capabilities discussed, it is essential that a flexible approach be taken in order to detect threats. Attackers explicitly craft attacks to evade different types of threat detection capabilities. Having layered, redundant threat detection capabilities is the best way to ensure that an attack is identified.

SECURITY CONTROL #3:

INTRUSION DETECTION CAN BE AUTOMATED USING THE FOLLOWING APPROACHES:

NETWORK-BASED INTRUSION DETECTION (NIDS)

Analyzes the network traffic to detect signatures of known attacks and patterns that indicate malicious activity. This is used to identify attacks, malware, policy violations and port scans.

HOST-BASED INTRUSION DETECTION (HIDS)

Analyzes system behavior and configuration to identify behavior that could indicate compromise. This includes the ability to recognize common rootkits, to detect rogue processes, and detect modification to critical configuration files.

CLOUD INTRUSION DETECTION

Cloud intrusion detection systems leverage the control plane in AWS and Azure, giving you full visibility into every operation that happens in your cloud “data center.”

Another important consideration is the placement of the threat detection capabilities that are deployed. Often these capabilities are only deployed on the perimeter of the organization with the thought that attacks only come from the outside. Modern attacks have broken this mold; today attackers leverage the fact that employees use their computers both inside and outside of the corporate firewall. A computer compromised while outside the perimeter now becomes a jumping off point for an attack from within the network. Threat detection should be deployed pervasively to address this. A good solution for threat detection will employ multiple techniques and provide substantial management capabilities to reduce the long term deployment costs.

SECURITY CONTROL #4:

HOW WILL I KNOW IF A BREACH HAS OCCURRED?

- If I do not detect the attack, how will I know an asset is compromised?
- If an asset is compromised, how can I address it before the breach expands?

Not all breaches are avoidable. Our efforts to make an impenetrable system will never be enough to close all attack vectors. We will always be faced with a risk management decision when it comes to determining whether a vulnerability in an asset running a critical business process is worth the cost of disrupting that process. Attackers know this and will use this to their advantage. To ensure that the advantage they gain from this is as minimal as possible, it is important for us to detect a breach as quickly as possible.

Understanding the behavior of our systems and monitoring that behavior for indications that a breach may have occurred is essential to an efficient response. For example, if an internal server that only sends and receives HTTP traffic suddenly opens up an outbound SSH tunnel to an external server, we have good reason to think that the server has been compromised. Understanding the behavior of your system as a whole includes understanding what assets communicate with one another, determining when services appear and disappear, and modeling network flow and protocol usage to detect anomalies.

SECURITY CONTROL #4:

MONITORING BEHAVIOR CAN BE PERFORMED WITH THE FOLLOWING APPROACHES

ACTIVE SERVICE MONITORING

Actively validate that services running on hosts are continuously available. This is done with a network-level handshake and response providing feedback if the service becomes available.

NETFLOW ANALYSIS

Analyzes the protocols and bandwidth used by each. This is done by capturing metadata from a TCP/IP stream, saving protocol information as well as calculating bandwidth usage.

NETWORK TRAFFIC CAPTURE

Captures the full TCP/IP stream. Allows for forensic storage of the stream so that detailed inspection can be performed if necessary.

HOST-BASED INTRUSION DETECTION

Can monitor the processes and resources used on a particular system. Detecting new processes or abnormal resource usage can be indicators of a compromise.

The information that can be gathered by behavioral monitoring tools must be used with caution. The systems that run in our organization are far from predictable—seasonal peaks such as an end-of-the-quarter sales effort can cause loads and behaviors never seen before. A good solution for behavioral monitoring will provide multiple mechanisms for collecting this data. In addition, it will provide a low-overhead mechanism for pervasive deployment in the organization.

SECURITY CONTROL #5:

WHAT ACTIONS ARE GOING TO HAVE THE MOST IMPACT ON MY SECURITY POSTURE?

- What do I do first?
- What data should I analyze today?
- Should I stop a recently observed attack or try and contain a newly discovered breach?

When deployed at scale, the essential controls described to provide asset discovery, vulnerability assessment, intrusion detection, and behavioral monitoring produce a vast amount of data. The comprehension and prioritization of that data needs to be automated for decisions to be made within a reasonable timeframe. In addition it is important for the data that is produced to be evaluated in conjunction with the data from the other security controls. Evaluation of each stream of data independently will lead to poor prioritization of efforts. For example, a new vulnerability is discovered on a host. Without having an understanding of what services that host provides or what attacks the host is being targeted with, it is hard to say whether it is more important to patch the vulnerability or to remove the malware just found on another server.

SECURITY CONTROL #5:

WHAT ACTIONS ARE GOING TO HAVE THE MOST IMPACT ON MY SECURITY POSTURE?

However, if we know that the host in question provides our business partners with the ability to refer customers to us and the server that has the malware infection is in our testing lab, then we can start to make better decisions. The ability to make sense of this data requires a system to consolidate and manage it all. That system must also provide normalization capabilities so that the data from disparate sources can be related to each other, and the full picture can be presented to the ultimate consumer of the information.

SECURITY CONTROL #5:

THERE IS ONLY ONE APPROACH TO AUTOMATING THE COMPREHENSION OF DATA TODAY:

SECURITY INFORMATION & EVENT MANAGEMENT (SIEM)

An informed management platform specifically designed for the evaluation of security information and events. Provides capabilities to normalize and analyze data from disparate sources and correlate it together to present a more complete picture of the incidents occurring in the overall system.

The most important aspect of a SIEM platform is how effectively the platform is able to correlate and present the data that is collected. The sole purpose of this platform is to increase the efficiency of the user who must analyze all of the data that is fed into it. Being able to associate the data together and respond to user queries is necessary for a user to be able to understand all of the data; however, it is not sufficient functionality to reach our goal of improving operator efficiency. The platform must be able to automate the correlation of the data in order to detect malicious behavior, large-scale attacks, and breaches. In a good solution, this correlation is kept up to date with the latest threat intelligence, allowing it to detect the newest methods of attackers and behaviors of malicious software.

Deployment of the **Essential Capabilities**

Security organizations are faced with a difficult challenge—if a major breach occurs, it will be their fault, regardless of the support the security team has received from the organization before that date. The capabilities described above are essential for a security team to either prevent breaches from occurring or to contain breaches before they become a major problem. However, security teams are often given little political or logistical support within an organization. Business concerns such as budget and resource allocation often take priority over proactive security. Given this limitation, security teams must be as efficient as possible while establishing a Security Operations Center. To get a complete picture and comprehensive prioritization, the security tools providing the essential capabilities must be pervasively deployed throughout the organization.

Deployment of the **Essential Capabilities**

To reduce the cost of this deployment, it is important to try and find ways to use redundant infrastructure whenever possible. Most of the security tools require access to the far reaches of the network, whether to monitor the network traffic or to gather data about a host. If each tool is independently deployed, then each tool will require configuration to understand your network topology and will require the proper credentials to gain access to every segment. In a similar fashion, many of these tools require rules or threat information to be periodically updated. If a common update mechanism can be used to provide rules to each of the tools, then the amount of configuration will be greatly reduced.

Another consideration is the cost of integrating the individual security controls that are deployed. As discussed above, a SIEM product is designed to consume and evaluate the data that is produced by these products. However, a SIEM platform is only a means to an end. It is intended for the integration of any type of data, and often requires substantial effort to integrate a new data source.

Conclusion

The capabilities discussed in this paper are the essential enablers for an organization to effectively and efficiently respond to threats and contain breaches. While the deployment of all of these capabilities is a daunting task, it is ultimately a cost- and time-saving project. Without having visibility into the actual threats facing your system, money will be inefficiently spent on compensating controls that might not have any impact. It is important for organizations to realistically evaluate how money is being spent, and critically ask whether there is data from their own environment that substantiates the spend on these projects. Establishing a Security Operations Center and implementing the technology and processes used to detect breaches and coordinate the appropriate response is the first step to long term, cost-effective management of risk.
